WORLD POPULATION GROWTH: ANALYSIS AND NEW PROJECTIONS OF THE UNITED NATIONS. By L. Jay Atkinson, Foreign Demand and Competition Division, Economic Research Service, U.S. Department of Agriculture. Foreign Agricultural Economic Report No. 129.

ABSTRACT

New projections to the year 2000 of world population growth, made by the United Nations, are discussed, and comparisons of growth in developed and developing countries, by 5-year periods, are made. Results of a regression analysis relating birth rates to death rates and income level are also presented.

KEYWORDS: Birth rates, death rates, food demand, population growth.

SUMMARY

World population growth has accelerated during the past three centuries. In this century, population growth speeded up in the decade of the fifties, as death rates declined and birth rates increased. According to the United Nations' medium variant projection of population growth, the growth rate for the world will have reached a peak plateau over the 1960-85 period. By 5-year periods, the highest growth rate is projected at 1.95 percent per annum for 1975-80, with the growth rate declining to 1.64 percent by 1995-2000.

Most of the acceleration in population growth has been attributable to a decline in death rates, with birth rates showing only limited changes until the past decade. Growth rates have dropped below 1 percent in developed countries but have

continued to expand above 2 percent in developing countries.

A cross section regression analysis of national birth rates shows that they are correlated directly with death rates and inversely with per capita income. For Asia and Africa, the principal relationship is between birth rates and death rates, whereas for Europe, birth rates are related mainly to income. For Latin America, birth rates are insignificantly related to death rates and only weakly related to income. By income levels for low-income countries, birth rates are directly related to death rates but not to income, whereas for high-income countries, birth rates are inversely related to income, and not related to death rates.

WORLD POPULATION GROWTH:

Analysis and New Projections by the United Nations

by L. Jay Atkinson

Economic Research Service

INTRODUCTION

Some of the anxiety of a few years ago about the projection of steadily rising rates of world population growth leading to an impossible situation rather soon has diminished. Nevertheless, world population continues to grow rapidly. Over any considerable period of time, population growth is a principal component of the demand for food and farm products. When we look 25 years ahead, the uncertainty about the increase in the demand for food is as much traceable to how fast population will grow as to how much income will increase. Whereas the income elasticity of demand for food is usually estimated to range from around 0.2 percent to as high as 0.4 percent, the population-food demand elasticity remains at 1.0, since the demand for food is directly proportional to population.

Recent world population growth has been slightly below the alltime peak reached in 1960-65, when the annual growth rate was 1.93 percent. It

eased to 1.87 percent in 1965-70, and then rose to 1.89 percent in 1970-75. But growth is accelerating again. For the 1975-80 period, the United Nations' medium projection is for annual growth of 1.95 percent. A slight easing of growth to 1.93 percent is projected for 1980-85, with a subsequent declining trend.

For the 25-year period 1960-85, the rate of world population growth will apparently have reached a peak plateau of a little under 2 percent per annum, with very minor variations for shorter periods. For the developed countries, however, the growth rate is declining, and it probably will have dropped to 0.83 percent for the 1980-85 period. Growth in the developing countries, on the other hand, is projected to peak in 1975-80 before beginning a slow decline, or in 1975-85 if the People's Republic of China (PRC) is excluded from the developing country group.

POPULATION GROWTH TRENDS

The trend in world population over the last 500 years has been one of accelerating growth (fig. 1 and table 1).¹ The 20th century has shown unprecedented growth, and the principal impetus has been a secular decline in death rates (fig. 2) and a slower, uneven decline in birth rates.

In the first decade of this century, the death rate was around 30 per 1,000 population, and the birth rate, about 40 per 1,000, giving a population growth rate of 1 percent annually. The population growth rate was sharply reduced in the next decade as World War I lowered birth rates and,

abetted by the influenza epidemic late in the decade, increased death rates.

In the twenties, there was an increase in the birth rate and a sharp drop in the death rate. This combination pushed world population growth back up to the 1-percent level, where it remained through the thirties and the forties, as first the depression and then World War II brought declines in the birth rate that about matched the secular decline in the death rate.

Then in the fifties, birth rates rose again—nearly reaching the level of the twenties—and death rates dropped sharply. This brought the rapid rise in world population that continued during the sixties as a gradual downturn in the birth rate was more than matched by a continued drop in death rates.

¹This section is based heavily on *World Population Growth and Response—1965-1975—a decade of global action*, Population Reference Bureau, Apr. 1976, p. 4.

PROJECTIONS

Based on the U.N. medium variant of world population growth, the prospects are that the peak population growth rate attained in the sixties is leveling off, although the growth rate is expected to edge up a bit in the next 10 years before beginning a gradual decline in the 1980's. By 5-year periods, the peak growth rate of 1.95 percent annually in 1975-80 is projected to ease successively to 1.93, 1.84, 1.75, and 1.64 during the rest of this century. Each of the three variants of the United Nations' projections shows some easing in world population growth during 1960-85, but each variant also shows different periods for peak growth. The low variant puts the 5-year peak in 1960-65, the medium locates it in 1975-80, and the high, in 1980-85 with a very slow subsequent easing.

The projected easing of population growth rates is important for many reasons, of which production of adequate food supplies is a principal one. Under the medium variant projection, however, the number of people added to the world's population each year will continue to expand throughout this century, reaching nearly 100 million annually by 2000. The low variant projection shows a considerable decline in the rate of world population growth by the end of the century—from 1.93 percent in the past 5 years to 1.30 percent for 1995-2000. But the number of added people each year would be as large then as now, and the world total would be 5.8 billion, or 1.8 billion more than at present. Thus, despite prospects for a slowed population growth rate, it will be a long time before there will be a reduced need for expanded production of food, clothing, housing, and educational services.

For the year 2000, the high and low projections for the world are 5.8 billion and 6.6 billion people, respectively. For the population in developing countries—excluding the People's Republic of China—the high and low projections are 4 billion and 3.5 billion people, respectively, reflecting a somewhat larger relative difference in high and low levels. The difference between the high and low projections for the PRC and India combined is 291 million people—which is about equal to the projected population of North America in the year 2000.

A brief look at the accuracy of earlier population projections in predicting 20th century trends reminds us of the uncertainty inherent in such forecasts. Projections of 30 to 40 years ago did not foresee the strong population trend of the past 25 years.

Going back just to the 1957 U.N. projection (fig. 3), we see that the intermediate projection of world population in the year 2000 was the same as

the current medium projection of 6¼ billion people. The difference between the high and low projections was much wider then—2 billion, compared with the difference of 800 million between the current high and low projections for 2000. Even the high 1957 projection was below actual growth to date. So, while the projection then was for a slower growth rate in the next two decades, it did not foresee the extent of slackening in the growth rate that is now expected.

Note on Data Quality and Another Interpretation. The data reported from all of the countries of the world are of widely varying quality. Some countries (e.g., PRC) have not taken a census in many years; others have limitations that affect an accurate count, and birth and death registrations are often unsystematic and incomplete.

Lester R. Brown has made an interpretation that is quite different from the implication in this bulletin. Using the same sources—that is the United Nations and the U.S. Bureau of the Census, "...except for those countries where more recent data are available from published studies or national surveys"² he finds that world population growth dropped sharply between 1970 and 1975. In that 5-year period, world population growth dropped from a 1.90-percent annual rate (1970) to a 1.64-percent annual rate (1975), according to Brown.

The latter growth rate is equal to the U.N.'s medium projected rate for 1995-2000. The annual increase in the world's population is estimated by Brown to decline from 69 million in 1970 to 64 million in 1975. This is in sharp contrast to the U.N. projections that shows a peak rate attained in 1975-80, followed by a slow decline to 1995-2000. However, the decline in the rate is so gradual that the annual increase in population gets larger during each 5-year period, reaching 98 million annually in 1995-2000.

Projections for 1950-2000

Now let us turn in more detail to the new U.N. projections by 5-year periods for 1950-2000 (table 1).

The strong growth projected for the developing countries contrasts with the slower growth for the developed countries (fig. 4). In 1975, the developing countries (including the PRC) had 71 percent of the world's population (table 2). By 2000, these same countries are projected to have 78 percent (although they may not all be categorized as developing countries by that time). Developing countries are projected to account for 90 percent of world

Developed countries:	1,132	29	1,360	22	228	10

Source: U.N. medium variant projection. United Nations Working Paper No. 55, May 1975.

population growth over the 25-year period, and for over 95 percent of world population growth during the nineties.

The decline in birth rates in the developing countries has about paralleled that of the developed countries (fig. 5). The big difference is in the level. Through the fifties and into the sixties, birth rates in developing countries were still above 40 per 1,000—not far from the rates that had prevailed almost universally until about the 18th century. Death rates in the developing countries were over 20 per 1,000 in the fifties, giving a population growth rate of nearly 2 percent per annum.

From 1950 to 1975, the decline in death rates exceeded the decline in birth rates in the developing countries, so that the population growth rate increased, reaching 2.31 percent per annum in the most recent 5-year period (table 3). Projections are for the population growth rate to rise to 2.37 percent in 1975-80, and then to begin declining as the drop in the birth rate exceeds that of the death rate. Population growth in developing countries is projected to drop to below 2 percent by the end of the century. However, by that time, these countries will have nearly 5 billion people and will be adding over 90 million each year. Thus, the absolute expansion will remain large for an extended period. If the PRC is excluded from the developing country group, as is often done in food demand calculations, the first slackening in the population growth rate of the developing countries is delayed another 5 years—that is, until after 1985 (table 3).

In the developed countries, only small further declines are expected in the birth rate, but the death rate may rise a little, reflecting the aging of the population. The net result is a drifting downward in the growth rate from about 0.85 percent annually at present to 0.60 percent by the end of the century.

Implications for Food Demand

As shown in figure 5, the population growth rate in developed countries dropped below 1 percent in 1965-70 and is drifting lower, whereas the growth rate in developing countries pushed up above 2 percent in the late fifties, has continued upward, and is projected to peak out at 2.37 percent in the current period, 1975-80.

As mentioned above, 90 percent of the growth in world population in the next 25 years is projected to occur in the developing countries (table 1). The International Food Policy Research Institute reports that of the projected increase in demand for food from 1970 to 1985 in the food-deficit countries, 80 percent will come from population growth.³ In the United States, food consumption has risen about 25 percent since 1960. While population has advanced nearly 20 percent, per capita consumption has risen only about 5 percent.

Income elasticities in developing countries are considerably higher than those of the developed countries, as indicated below:⁴

Income elasticities for—

	Total food calories	Calories of animal origin	Animal protein
Developed countries	.08	.24	.28
Developing countries	.22	.58	.56

World Birth, Death, and Growth Rates from 1950 to 2000

Figure 5

Coarse grains are an important part of the diet for an estimated 750 million people throughout the world. Starchy roots, bananas, and plantains are important throughout the tropics. These foods are "inferior" goods in the economic sense, in that as people's incomes rise, they consume less, not more,

of them, substituting preferred foods. For the grains, the preference is very marked for food grains, chiefly rice and wheat, over the coarse grains. This is both observable by country and within countries by low income and high income groups.⁵

BIRTHS, DEATHS, AND INCOME

We now want to look at the relationship between birth rates and death rates and income level or development. These relationships are discussed over periods of time and then examined in a cross section analysis.

Historical Relationships

The general, historical pattern of population and development is that death rates fall more rapidly and earlier than do birth rates as countries begin to develop economically. Between the time that death rates have fallen and the time that birth rates make an appreciable decline, there is a transition period of rapid population growth. As coun-

tries continue to develop and incomes rise, birth rates decline faster than death rates, slowing the population growth rate.

The developed countries have largely completed this transition and now have low birth rates, low death rates, and slow population growth. The main exceptions are the relatively new, lightly populated countries, such as Australia and New Zealand, where birth and population growth rates are still relatively high.

Most of the developing countries are in the transitional growth stage and seem to be passing through it rather slowly, obtaining population growth rates which have reached unprecedented highs. Death rates have fallen rather steeply and are expected to continue declining to the end of this century (fig. 5). Birth rates have declined less

⁵Ibid., p. 41, footnote.

rapidly, although they are projected to fall as fast as death rates within the next decade or so.

Recently developed countries, such as Japan and Israel, have had sharp drops in birth rates and rapid advances in incomes. A few of the developing countries that are making rapid progress are having appreciable declines in birth rates, especially the small, heavily populated countries in the Orient—South Korea, Taiwan, and the city states of Hong Kong and Singapore. Other populous, rapidly developing countries, especially Mexico and Brazil, and to a lesser extent Thailand, still have unusually high birth rates. Since they have developed rapidly, they have low death rates and hence, accelerated population growth rates.

This relationship between births, deaths, and development or income has not yet fully materialized for the developing countries, since most have registered little decline in birth rates. In the past 25 years, the larger decline in birth rates has occurred in developed countries (fig. 5). What is empirical and can be investigated is the present situation. To what extent are present birth rates related to death rates and to per capita income or to gross domestic product?

To answer this question, we have made a cross-section analysis of birth rates as a function of death rates and of either per capita disposable income (DI) or per capita gross domestic product (GDP).

It is not postulated that the death rate and the income variables are the "cause" of variations in the birth rate. However, the influences that affect declines in death rates and advances in income appear to also affect declines in birth rates, perhaps with some lag, especially in the case of income advances. In this analysis, income is considered to be a proxy variable for economic development.

Declines in death rates may have some influence on decisions about births, and these declines are likewise a proxy for general health and sanitation improvement. In the regression analysis, death rates are not too highly correlated with disposable income ($R^2 = .11$) or with GDP.

It is easy to think of a list of relevant variables other than income and death rates that may affect birth rates. Of these, an educational attainment index is a possibility, and such series have been calculated from time to time. Another possibility is some index of income distribution, or even a medium instead of a mean income. If some index of birth control usage or expenditures were available, especially for developing countries, this might be helpful.

Despite these reservations, the two independent variables chosen for this analysis—death rates and either average per capita disposable income or GDP—show considerable correlation with birth

rates and provide some relationships that seem appropriate.

The regressions were first tried on countries for which disposable income data were available, and then on the larger number of countries for which mean per capita GDP data were available. Since results were quite similar, only a few comparisons of the significant income and GDP equations will be discussed. The larger number of countries with data for GDP than for disposable income is especially useful for regressions for regions and income classes where the number of observations is rather small. For the world, however, the disposable income correlations ($R^2 = .73$) are somewhat higher than for those with GDP ($R^2 = .67$). Perhaps some of the countries reporting GDP but not disposable income have less accurate data.

We used the latest available U.N. demographic estimates, which are for 1970-75, and disposable income or GDP for the years calculated in the latest U.N. national income accounts volume, which is for 1974.⁶ For the disposable income per capita, we tried varying time lags between income and birth rates.

Results of Regression Analysis

Results of the regression analysis with birth rates as the dependent variable and death rates and either disposable income or GDP as independent variables are reported first for all countries (world) for which data are available. Then, results by continents and by income level are discussed. The equations are shown in table 4.

Both the death rate and per capita disposable income are strongly related to births. Income is the more important in explaining variance in the birth rate; in both the linear and the natural log equations, income accounts for about twice as much variation in birth rates. The coefficient of variation (CV) (the standard deviation divided by the mean) of income is more than twice as great as the CV for either birth or death rates. The CV for the birth rate is 43 percent; for the death rate, 40 percent; and for 1970 per capita income, 94 percent.

In the linear version, each change of 1 death per 1,000 population is accompanied by a similar change of 1 birth per 1,000 population. And each change of \$1,000 in per capita income or GDP is associated with a change in the birth rate of around 8 per 1,000 population for disposable income and 6 per 1,000 for GDP. The values of the coefficients in the vicinity of the means for the other disposable income equations are not very different for each of the equations tested. These

28. For GDP 70 more than 500	48	.30	Semi-L Births = 79.723 + .2241 Deaths - 7.9653 LGDP 70 (3.8) (.6) (-4.4)
29. For GDP 70 more than 500	48	.37	Log-Log LBirths = 5.8015 - .10995 L Deaths - .33857 LGDP 70 (10.3) (-.74) (-5.06) R for LB and LDea is low (-.12) but LB and LGDP have high correlation (R = .60)
30. For GDP 70 less than 1000	104	.55	Semi-L Births = 41.0438 + .7709 Deaths - 2.2930 LGDP 70 (5.4) (5.8) (-2.1)
31. For GDP 70 less than 1000	104	.56	Log-Log LBirths = 3.1036 + .3332 L Deaths - .0575 LGDP 70 (10.8) (6.37) (-1.86) Both these LGD have higher R ² with Deaths than with Births
32. For GDP 70 more than 1000	26	.66	Log-Log LBirths = 6.4384 - 1.1539 L Deaths - .1260 LGDP 70 (8.2) (-6.6) (-1.4)

Note: Numbers in parenthesis below the coefficients are the t-values for standard error. The t-values of 2 or more are highly significant.

included log equations and semi-log equations with logs for births and deaths in the one case and for income in the other. All four of the variants explained around 70 percent of the variation in birth rates or a little more (R^2 ranged from .70 to .73). The variation in birth rates explained by the GDP equation was somewhat less ($R^2 = .67$), but with the larger number of observations, the error terms for each of the variables was just as satisfactory ($t = 8$ or 9).

Another question investigated was the appropriate lag between income and its effects on birth rates. We tried a lag of about a year, of over 2 years, and of about 10 years. The lag of a year was too short a time, and there was little difference between the 2-year and the 10-year lags in the correlation with births. The inverse relationship between births and incomes was highly significant and accounted for over half the variation in birth rates between countries.

Our sample consisted of 65 countries for the disposable income equations and 133 for the GDP equations. We chose all the countries for which births rates, death rates, and disposable income per capita for 1963, 1970, and 1972 were available for the disposable income regressions and those for which GDP for 1970 was available for that set. Each of the samples included most of the populous countries. There were enough countries to run separate regressions for the principal developing continents, and one for the developed countries and also for low-income and high-income countries. Since there was little difference between the linear and the log equations, and the latter were sometimes more appropriate, the log form is usually discussed.

In both Asia and Africa, a higher proportion of the variance in birth rates was explained by the regression ($R^2 = .75$ for Asia and $.79$ for Africa). And in each case, the principal variable was the death rate. In each continent, 14 countries were in the sample, with variations of 10 percent in death rates associated with around 5-percent variations in the same direction in birth rates. The coefficients were similar for the GDP equations, but the correlations were somewhat lower ($R^2 = .55$ to $.60$).

Income differences between countries were not significantly associated with differences in birth rates in either Asia or Africa, by any standard. In Africa, the very small coefficient had the wrong sign—that is, it was positive—but it was not statistically significant ($t = 1.1$). In Asia the coefficient had the right sign, but was small and not significant. We report these relationships without being sure why variations in deaths between countries in Asia and Africa are so closely related to birth rates or why variations in income between countries appear to have so little relation to variations in birth rates.

In Latin America, the relationship between birth rates and death rates was insignificant. Birth rates were rather weakly but significantly correlated with disposable income or GDP, in the expected inverse relationship, with changes of 10 percent in income associated with changes in the other direction of 2 percent in the birth rate ($t = -2.2$). However, income or GDP was more closely correlated with death rates ($R^2 = .50$) than with birth rates ($R^2 = .36$). All in all, the equation explained less of the variation in birth rates ($R^2 = .38$) than it did for the other continents.

For Europe, there was a strong inverse correlation ($t = -11$) between birth rates and income and a weak and illogical one between birth rates and death rates that is not significant ($t = -1.8$). The correlation is good ($R^2 = .74$). Each 10-percent change in disposable income was associated with a 4-percent inverse change in birth rates.

As a partial check, we computed separate regressions for countries with per capita incomes of less than \$500 in 1970 and for those with incomes of over \$500, and repeated the process substituting \$1,000 for the separate regression breaks.

For countries with disposable income per capita of not more than \$500 in 1970, income variation between countries was not significantly related with variations in birth rates. However, death rates were correlated ($R^2 = .55$) with birth rates. On a linear basis, each change of 1 per 1,000 in death rates was associated with an average change in birth rates of the same size in the same direction. Birth rates were more than 3 times death rates; on a log or relative basis, each change of 10-percent in death rates was associated with a 3-percent change in birth rates. The GDP equations were consistent.

For countries with per capita incomes above \$500 in 1970, death rates were insignificant in explaining birth rates, and changes in incomes were inversely associated with changes in birth rates. The principal deviations were South Africa, Libya, Kuwait, and Venezuela, where the birth rate has remained very high despite higher average incomes (fig. 6). For South Africa, the birth rate is little affected, perhaps because of a skewed income distribution, with whites having larger incomes among a predominately black population. Kuwait, Venezuela, and Libya were not included in some of the correlations because they were so unusual that the high income had been little reflected in a declining birth rate. Perhaps the skewed distribution was important in these countries, too.

For the regressions based on disposable income or GDP of less than or more than \$1,000 countries with less than \$1,000 had similar positive birth-death correlations similar to those in countries under the \$500 break, but for countries with an income break under \$1,000, income and birth rates are just significantly inversely related. For incomes

Birth Rates by Gross Domestic Product Per Capita in Dollars, 1970

Figure 6

over \$1,000, the size of the sample drops, and the results are inconclusive, with some inverse correlation between births and deaths that is unexpected and appears to be due to bad data.

Inspection of the data for countries with GDP of more than \$1,000 shows that the unexpected relationships between birth rates and the two variables death rates and DI occur primarily in a group of non-European countries. This heterogeneous group with high incomes includes OPEC

countries and the sparsely populated, late-developing countries such as Australia and New Zealand, as well as a few densely populated ones. In general, this group reports high income and relatively high birth rates and low death rates—sometimes incredibly low death rates. For such a heterogeneous group, more complex relationships are required to relate to variations in births.
